26.4 — Class template specialization

ALEX O DECEMBER 15, 2023

In the previous lesson 26.3 -- Function template specialization (https://www.learncpp.com/cpp-tutorial/function-template-specialization/), we saw how it was possible to specialize functions in order to provide different functionality for specific data types. As it turns out, it is not only possible to specialize functions, it is also possible to specialize classes!

Consider the case where you want a class that stores 8 objects. Here's a simplified class template to do so:

```
#include <iostream>
template <typename T>
class Storage8
private:
   T m_array[8];
    void set(int index, const T& value)
        m_array[index] = value;
    const T& get(int index) const
        return m_array[index];
};
int main()
    // Define a Storage8 for integers
    Storage8<int> intStorage;
    for (int count{ 0 }; count < 8; ++count)</pre>
        intStorage.set(count, count);
    for (int count{ 0 }; count < 8; ++count)</pre>
        std::cout << intStorage.get(count) << '\n';</pre>
    // Define a Storage8 for bool
    Storage8<bool> boolStorage;
    for (int count{ 0 }; count < 8; ++count)</pre>
        boolStorage.set(count, count & 3);
    std::cout << std::boolalpha;</pre>
    for (int count{ 0 }; count < 8; ++count)</pre>
        std::cout << boolStorage.get(count) << '\n';</pre>
    return 0;
```

This example prints:

0			
1			
2			
3			
4			
5			
6			
7			
false			
true			
true			
true			
false			
true			
true			
true			

While this class is completely functional, it turns out that the implementation of Storage8<bool> is more inefficient than it needs to be.

Because all variables must have an address, and the CPU can't address anything smaller than a byte, all variables must be at least a byte in size.

Consequently, a variable of type bool ends up using an entire byte even though technically it only needs a single bit to store its true or false value! Thus, a bool is 1 bit of useful information and 7 bits of wasted space. Our Storage8<bool> class, which contains 8 bool, is 1 byte worth of useful information and 7 bytes of wasted space.

As it turns out, using some basic bit logic, it's possible to compress all 8 bools into a single byte, eliminating the wasted space altogether. However, in order to do this, we'll need to revamp the class when used with type bool, replacing the array of 8 bool with a variable that is a single byte in size. While we could create an entirely new class to do so, this has one major downside: we have to give it a different name. Then the programmer has to remember that Storage8<T> is meant for non-bool types, whereas Storage8Bool (or whatever we name the new class) is meant for bool. That's needless complexity we'd rather avoid. Fortunately, C++ provides us a better method: class template specialization.

Class template specialization

Class template specialization allows us to specialize a template class for a particular data type (or data types, if there are multiple template parameters). In this case, we're going to use class template specialization to write a customized version of Storage8
that will take precedence over the generic Storage8<T> class.

Class template specializations are treated as completely independent classes, even though they are allocated in the same way as the templated class. This means that we can change anything and everything about our specialization class, including the way it's implemented and even the functions it makes public, just as if it were an independent class. Note that a class template specialization requires the class that it is specializing to be defined first.

Here's an example of a specialized Storage8<bool> class:

```
#include <cstdint>
// First define our non-specialized class template
template <typename T>
class Storage8
private:
    T m_array[8];
public:
    void set(int index, const T& value)
    {
        m_array[index] = value;
    const T& get(int index) const
        return m_array[index];
};
// Now define our specialized class template
template <> // the following is a template class with no templated parameters
class Storage8<bool> // we're specializing Storage8 for bool
// What follows is just standard class implementation details
    std::uint8_t m_data{};
public:
    // Don't worry about the details of the implementation of these functions
    void set(int index, bool value)
        // Figure out which bit we're setting/unsetting
        // This will put a 1 in the bit we're interested in turning on/off
        auto mask{ 1 << index };</pre>
        if (value) // If we're setting a bit
            m_data |= mask; // use bitwise-or to turn that bit on
        else // if we're turning a bit off
            m_data &= ~mask; // bitwise-and the inverse mask to turn that bit off
    }
    bool get(int index)
        // Figure out which bit we're getting
        auto mask{ 1 << index };</pre>
        // bitwise-and to get the value of the bit we're interested in
        // Then implicit cast to boolean
        return (m_data & mask);
};
// Same example as before
int main()
    // Define a Storage8 for integers (instantiates Storage8<T>, where T = int)
    Storage8<int> intStorage;
    for (int count{ 0 }; count < 8; ++count)</pre>
        intStorage.set(count, count);
    for (int count{ 0 }; count < 8; ++count)</pre>
    {
        std::cout << intStorage.get(count) << '\n';</pre>
    }
    // Define a Storage8 for bool (instantiates Storage8<bool> specialization)
    Storage8<bool> boolStorage;
    for (int count{ 0 }; count < 8; ++count)</pre>
    {
        boolStorage.set(count, count & 3);
    std::cout << std::boolalpha;</pre>
    for (int count{ 0 }; count < 8; ++count)</pre>
        std::cout << boolStorage.get(count) << '\n';</pre>
    return 0;
```

First, note that our specialized class template starts off with template<>. The template keyword tells the compiler that what follows is a template, and the empty angle braces means that there aren't any template parameters. In this case, there aren't any template parameters because we're replacing the only template parameter (T) with a specific type (bool).

Next, we add <bool> to the class name to denote that we're specializing a bool version of class Storage8.

All of the other changes are just class implementation details. You do not need to understand how the bit-logic works in order to use the class (though you can review <u>O.2 -- Bitwise operators (https://www.learncpp.com/cpp-tutorial/bitwise-operators/)</u> if you want to figure it out, but need a refresher on how bitwise operators work).

. . .

0

Note that this specialization class utilizes a std::uint8 t (1 byte unsigned int) instead of an array of 8 bool (8 bytes).

Now, when we instantiate an object type Storage<T>, where T is not a bool, we'll get a version stenciled from the generic templated Storage8<T> class. When we instantiate an object of type Storage8<bool>, we'll get the specialized version we just created. Note that we have kept the publicly exposed interface of both classes the same -- while C++ gives us free reign to add, remove, or change functions of Storage8<bool> as we see fit, keeping a consistent interface means the programmer can use either class in exactly the same manner.

As you might expect, this prints the same result as the previous example that used the non-specialized version of Storage8<bool>:

0		
1		
2		
3		
4		
5		
6		
7		
false		
true		
true		
true		
false		
true		
true		
true		

Specializing member functions

In the previous lesson, we introduced this example:

```
#include <iostream>
template <typename T>
class Storage
private:
   T m_value {};
public:
   Storage(T value)
      : m_value { value }
    void print()
         std::cout << m_value << '\n';</pre>
};
int main()
    // Define some storage units
    Storage i { 5 };
Storage d { 6.7 };
    // Print out some values
    i.print();
    d.print();
}
```

Our desire is to specialize the print() function so that it prints doubles in scientific notation. Using class template specialization, we could define a specialized class for Storage<double>:

. . .

```
#include <iostream>
template <typename T>
class Storage
{
private:
   T m_value {};
public:
   Storage(T value)
      : m_value { value }
    }
    void print()
        std::cout << m_value << '\n';</pre>
};
// Explicit class template specialization for Storage<double>
// Note how redundant this is
template <>
class Storage<double>
private:
    double m_value {};
public:
    Storage(double value)
      : m_value { value }
    }
    void print();
// We're going to define this outside the class for reasons that will become obvious shortly
void Storage<double>::print()
    std::cout << std::scientific << m_value << '\n';</pre>
int main()
    // Define some storage units
    Storage i { 5 };
    Storage d { 6.7 }; // uses explicit specialization Storage<double>
    // Print out some values
    i.print(); // calls Storage<int>::print (instantiated from Storage<T>)
    d.print(); // calls Storage<double>::print (called from explicit specialization of Storage<double>)
}
```

However, note how much redundancy there is here. We've duplicated an entire class definition just so that we can change one member function!

Fortunately, we can do better. C++ does not require us to explicitly specialize Storage<double> to explicitly specialize Storage<double> to explicitly specialize Storage<double> from Storage<T>, and provide an explicit specialization of just Storage<double>::print()! Here's what that looks like:

```
#include <iostream>
template <typename T>
class Storage
{
private:
    T m_value {};
public:
   Storage(T value)
       : m_value { value }
     void print()
         std::cout << m_value << '\n';</pre>
};
template<>
void Storage<double>::print()
     std::cout << std::scientific << m_value << '\n';</pre>
int main()
     // Define some storage units
    Storage i { 5 };
Storage d { 6.7 }; // will cause Storage<double> to be implicitly instantiated
     // Print out some values
    i.print(); // calls Storage<int>::print (instantiated from Storage<T>)
d.print(); // calls Storage<double>::print (called from explicit specialization of Storage<double>::print())
}
```

That's it!
